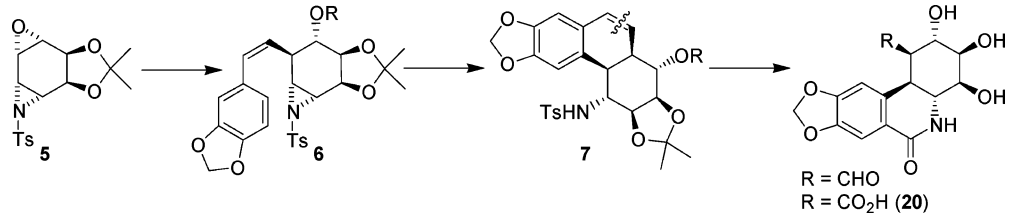
ABSTRACT



Solid-state silica-gel-catalyzed opening of aziridine 6 provided phenanthrene 7, whose oxidative cleavage, recyclization, and further elaboration furnished the C-1 aldehyde and carboxylic acid derivatives of 7-deoxypancratistatin for potential analogue synthesis.

Since the first asymmetric synthesis of pancratistatin that we published in 1995,[1] we have devoted considerable effort to multigenerational design of and improvements[2] in approaches to the total synthesis of Amaryllidaceae constituents[3] and their unnatural derivatives.[4] In collaboration with Pettit's group at Arizona State University, we have focused on designs to produce a variety of derivatives[5] containing the minimum pharmacophore but with better bioavailability or solubility than the otherwise very potent natural products such as pancratistatin (**1**), narciclasine (**2**), or their 7-deoxy analogues 7-deoxypancratistatin (**3**) and lycoricidine (**4**). These constituents are shown in Figure 1 along with an indication of the structural requirements for activity as elucidated through the efforts of Pettit and others.[6]

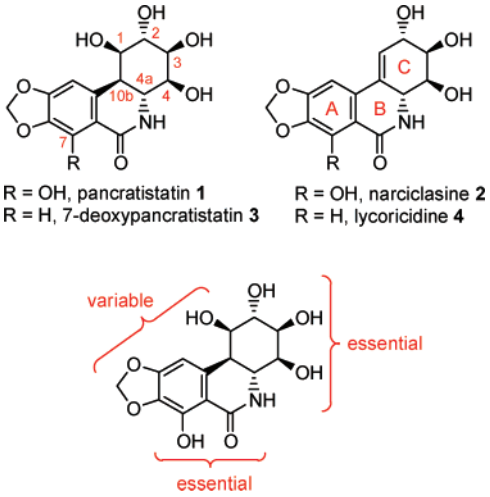

Figure 1. Pancratistatin and congeners; the structural and functional requirements for a minimum pharmacophore.

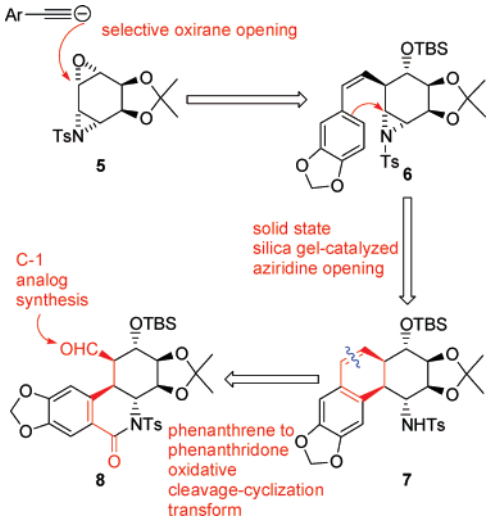

Figure 2. Design strategy toward 7-deoxypancratistatin and its C-1 analogues based on oxidative cleavage of the phenanthrene core and recyclization to the phenanthridone.

Pancratistatin and narciclasine are highly active against many cancer cell lines: murine P388 lymphocytic leukemia; human cancer cells: pancreas BXPC-3, breast MCF-7, CNS SF-268, lung NCI-H460, colon KM20L2, and prostate DU-145. Although the exact mode of action remains unknown for pancratistatin, narciclasine is believed to inhibit peptide bond formation in eukaryotic ribosomes.[7] Lycoricidine and 7-deoxypancratistatin are significantly less active, probably because of the absence of the hydrogen-bonded donor−acceptor pair in the phenanthridone functionality.

As C-1 substitution does not appear to be detrimental to biological activity,[8] we considered preparation of compounds with varied functionality at this position. To this end we envisioned a new approach that would provide an aldehyde functionality at C-1, well suited for further derivatization. The new strategy, portrayed in Figure 2, is based on the recently discovered solid-state silica-gel-catalyzed opening of aziridines with carbon nucleophiles.[4c] The approach relies on the regioselective opening of epoxy aziridine **5**[9,2f] with aluminum acetylide, reduction of the alkyne to the cis olefin in **6**, solid-state cyclization to the complete phenanthrene core **7**, and oxidative cleavage with concomitant recyclization and selective oxidation to the phenathridone **8**, which possesses the complete nucleus of pancratistatin-type compounds. The recyclization strategy not only provides the C-1 aldehyde for further functionalization and production of analogues but also allows the conversion of this compound to 7-deoxypanacratistatin by a more efficient protocol than used in our previous syntheses. In this manuscript we report the total synthesis of the C-1 carboxylic acid analogue of 7-deoxypancratistatin and outline the potential of a library-type approach to C-1 derivatives from aldehyde **8**.

The synthesis began with the preparation of homochiral epoxy aziridine **5**[9] from bromobenzene by previously established protocols.[10] Selective opening of the oxirane ring was accomplished with the aluminum acetylide derived from **11**, generated *in situ*, providing after protection the silyl ether **12**. Borane reduction furnished the cis alkene **6**, which was adsorbed on silica[4c] and heated without solvent at 120 °C for 24 h to provide a 52% yield of phenanthrene **7**, as shown in Scheme 1.

Phenanthrene **7** was converted to the phenanthridol skeleton **15** either by direct ozonolysis of **7** or by a three-step procedure consisting of OsO_4-mediated oxidation to the stage of over-oxidized keto alcohol **13** (OsO_4/NMO, 89%), followed by reduction and periodate cleavage to dialdehyde **14**, which immediately cyclized to the hemiaminal **15**. The three-step procedure produced **15** in an overall yield of 82% from **7**. Oxidation with IBX provided the complete phen-

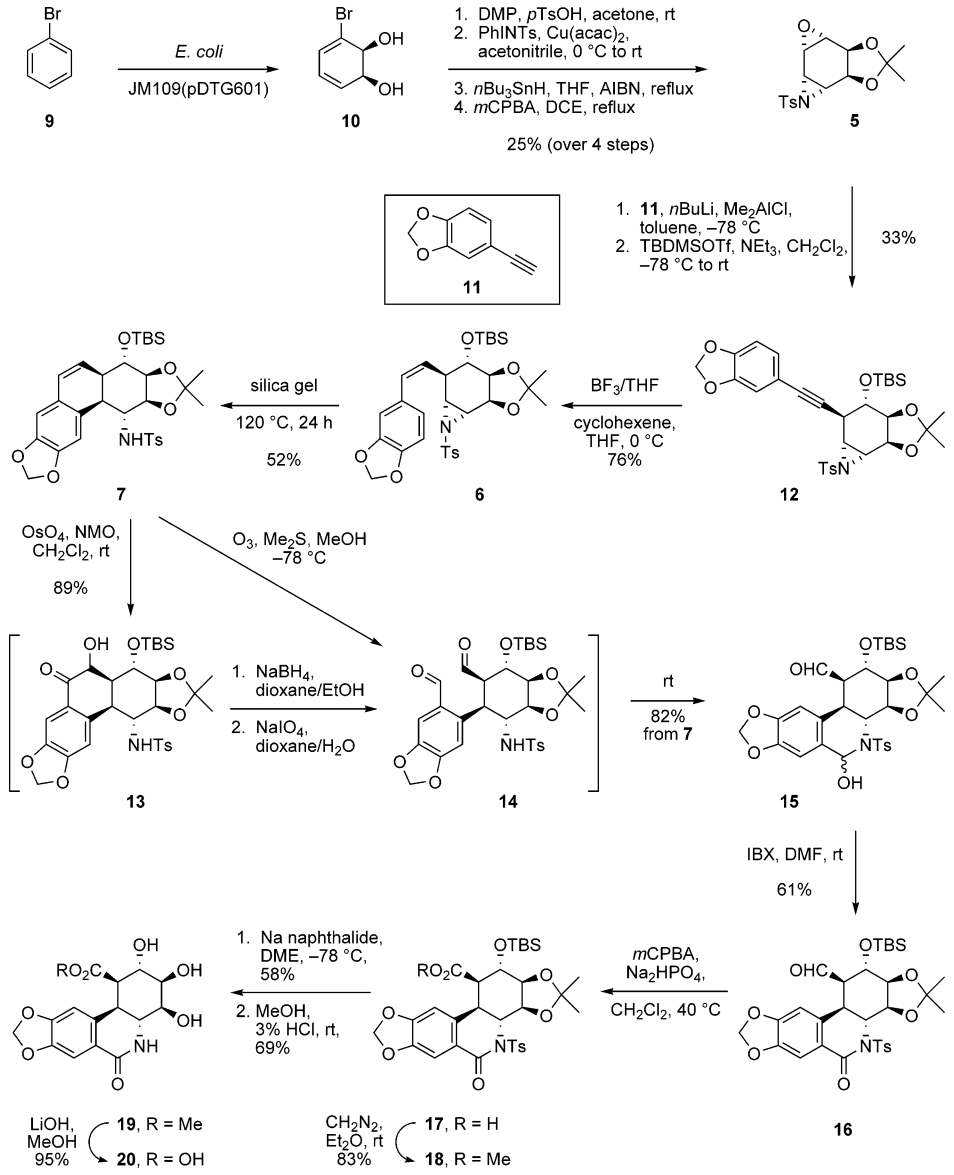
Scheme 1



athridone skeleton **16** in six steps from epoxy aziridine **5** or ten steps from bromobenzene. Further oxidation of the aldehyde with *m*-CPBA furnished in 85% yield the C-1 carboxylic acid **17**, which was then elaborated to the fully hydroxylated stage of **20**. Because of the polarity of the final product, subsequent preparation proceeded to the methyl ester **18**, obtained in 83% yield from acid **17** by treatment with diazomethane. Ester **18** was then converted to the fully hydroxylated species **19** by reductive detosylation and deprotection prior to the final hydrolysis with LiOH in MeOH. The synthesis of the C-1 acid proceeded in 15 steps from bromobenzene.

Future efforts will focus on the conversion of **19** by oxidative decarboxylation[11] to the conduramine derivative **21**, a compound whose *N*-methoxybenzyl derivative has been converted to 7-deoxypancratistatin,[12] Figure 3. Aldehyde **16**
